## Abstract

The Mexico City Metropolitan Area (MCMA) study in April 2003 had measurements of most atmospheric constituents including OH and HO<sub>2</sub>. It provided a unique opportunity to examine atmospheric oxidation in a megacity that has more pollution than typical US and European cities. OH typically reached 0.35 pptv ( $\sim 7 \times 10^6 \text{ cm}^{-3}$ ), comparable to amounts observed in US cities, but HO<sub>2</sub> reached 40 pptv in the early afternoon, more than observed in most US cities. A steady-state photochemical model simulated the measured OH and HO<sub>2</sub> for day and night to within combined measurement and modeling uncertainties for 2/3 of the results. For OH, measured = 0.65 (modeled) + 0.026 pptv, with  $R^2=0.80$ . For HO<sub>2</sub>, observed = 0.70 (modeled) + 3.4 pptv, with  $R^2=0.64$ . Measurements tended to be higher during night and rush hour; the model was higher by  $\sim 30\%$  during midday. With a large median measured OH reactivity of more than  $120 \text{ s}^{-1}$  during morning rush hour, median ozone production from observed HO<sub>2</sub> reached 50 ppb  $\text{hr}^{-1}$ ; RO<sub>2</sub> was calculated to have a similar ozone production rate. For both the HO<sub>2</sub>/OH ratio and the ozone production, the measured values have the essentially same dependence on NO as the modeled values. This similarity is unlike other urban studies in which the NO-dependence of the measured HO<sub>2</sub>/OH ratio was much less than the modeled ratio and the ozone production rate that was calculated from measured HO<sub>2</sub> unexpectedly appeared to increase as a function of NO with no obvious peak.

## 1. Introduction

Megacities contain not only millions of people but also elevated levels of airborne pollutants. These pollutants are generated by the transportation and industry necessary to support these millions. The fast chemistry that transforms primary pollutant emissions of nitrogen oxides (NO<sub>x</sub>) and volatile organic compounds (VOCs) is initiated by reactions of the hydroxyl radical, OH, with VOCs. The subsequent reactions produce

the hydroperoxyl radical, HO<sub>2</sub>, which reacts with NO to reform OH and create NO<sub>2</sub>, resulting in the production of the pollutant ozone (O<sub>3</sub>). Low volatility VOCs are also generated, resulting in the formation of secondary organic aerosol mass. Together, OH and HO<sub>2</sub>, called HO<sub>x</sub>, form a rapid reaction cycle that drives this atmospheric chemistry.

Several field studies that include HO<sub>x</sub> measurements have been conducted in urban environments in the United States, including Los Angeles, California (George et al., 1999), Nashville, Tennessee (Martinez et al., 2003), Houston, Texas (Martinez et al., 2002) and New York City, New York (Ren et al., 2003a). Field studies with HO<sub>x</sub> measurements have also been conducted in urban air in Europe as well, including Berlin, Germany (Volz-Thomas et al., 2003, and accompanying papers) and Birmingham, United Kingdom (Heard et al., 2004; Emmerson et al., 2005). The Mexico City Metropolitan Area (MCMA), a megacity, has more pollution than any of these other urban environments (Molina and Molina, 2002).

OH and HO<sub>2</sub> and other atmospheric constituents important for studying atmospheric oxidation were measured during the Mexico City Metropolitan Area 2003 (MCMA-2003) study, which was held in the MCMA during April 2003. MCMA is at a high altitude (~2240 m) near the equator at 19°25' N latitude. At this high altitude and low latitude, intense solar radiation penetrates to the surface causing active photochemistry. In addition to the radiation, the area's orography, with mountains to the west, east, and south of the metropolitan area, traps pollutants in the basin. As a result, MCMA experiences high pollution levels. These simultaneous measurements were an opportunity to develop a better understanding of MCMA's high pollution levels of ozone and secondary particulate matter. They also stretch the envelope of polluted environments that have been studied with a complete measurement suite that includes measurements of the radicals OH and HO<sub>2</sub>.

2. Description of the MCMA 2003 study

2.1. Site description

Measurements of OH and HO<sub>2</sub> were made from the roof of the building that houses the National Center of Investigation and Environmental Qualification (CENICA) on the Iztapalapa campus of the Autonomous Metropolitan University in Iztapalapa, Mexico City. Iztapalapa lies in the south-central MCMA, due south of the downtown area by ~7 km. The university is located in a semi-residential and semi-industrial area. To the west and south of the university are mainly residential areas; to the north and east are several factories and industries.

Northerly (southward) wind, which is usually the dominant surface-wind direction during the daytime hours, generally brings air from the downtown to this site. The winds from all other directions bring air from the surrounding suburbs to the site. In contrast to mid-latitude megacities, high pollution episodes can occur year-round in the MCMA because the subtropical highs that dominate the weather throughout the year are conducive to active photochemistry. During the winter and spring months, the area is normally under an anticyclone with light winds and clear skies. As a result, strong surface-based inversions usually persisted several hours into the morning. Strong solar heating eventually breaks down the inversion and pollutants then mix into a very deep boundary layer of around four km. This study was held in April to avoid the wetter summer months (June–September) because clouds and precipitation inhibit strong photochemistry (Molina and Molina, 2002). However, in 2003, the summertime pattern began in April, resulting in frequent clouds and some rain in the afternoon.

2.2. GTHOS (Ground-based Tropospheric Hydrogen Oxides Sensor)

OH and HO<sub>2</sub> were measured by the Penn State Ground-based Hydrogen Oxides Sensor, called GTHOS. A brief description of the measurement technique and instrument is given here; a full description can be found in Faloon et al. (2004). GTHOS mea-

Interactive Discussion

surement of OH and HO<sub>2</sub> is based on FAGE (Fluorescence Assay by Gas Expansion) (Hard et al., 1984). The air sample is drawn through an orifice (1.0 mm diameter) into a low-pressure chamber at a pressure of 4–5 hPa. As the air passes through a laser beam, OH is excited by the laser and then detected at a wavelength near 308 nm. Collisional quenching of the excited state is slow enough at the chamber pressure that the weak OH fluorescence extends beyond the prompt scattering (Rayleigh and wall scattering) and is detected with a time-gated microchannel plate (MCP) detector.

OH is detected in the first of two detection axes. In a second axis, HO<sub>2</sub> is chemically converted to OH by reaction with reagent NO that is added to the flow between the two axes. The resultant OH is then detected by LIF. The laser wavelength is turned on and off resonance with an OH transition every 10 s. The OH fluorescence signal is the difference between on-resonance and off-resonance signals.

GTHOS was calibrated before, during, and after the study using the techniques described in Faloona et al. (2004). The upper-limit of the absolute calibration uncertainty was estimated at ±32% (at the 95% – 2  $\sigma$ -confidence level). The OH detection limit can be defined from twice the standard deviation of the background signal and was 0.01 part per trillion by volume, or pptv, ( $\sim 2 \times 10^5 \text{ cm}^{-3}$ ) for a 1-min integration period. The HO<sub>2</sub> detection limit (with 2 $\sigma$ -confidence, 1-min integration time) was estimated to be 0.1 pptv ( $\sim 2.0 \times 10^6 \text{ cm}^{-3}$ ).

During the campaign in Mexico City, GTHOS was mounted approximately 18 m above the ground on the third level of a scaffolding tower (Fig. 1). Ambient air was pulled through the system by a vacuum pump that was located directly beneath the measurement tower. The electronics and calibration equipment were housed in an air-conditioned hut that was directly adjacent to the tower.

### 2.3. TOHLM (Total OH Loss Measurement)

The first-order OH loss rate, called the OH reactivity, was measured with the Total OH Loss Measurement instrument (TOHLM) (Kovacs and Brune, 2001; Kovacs et al., 2003; DiCarlo et al., 2004). It was mounted on the first level of the tower, approximately

Interactive Discussion

14 m above the ground. The inlet hose for TOHLM was mounted just below the inlet of GTHOS on the third level of the tower.

The TOHLM method is analogous to the discharge-flow technique used in laboratory kinetics studies. OH is generated at mixing ratios of a few 10's of parts per trillion by volume (pptv) by ultraviolet light from a mercury lamp. This light photodissociates water vapor, creating OH and H in a nitrogen flow inside a 1-cm diameter movable tube. H rapidly reacts with trace O<sub>2</sub> in the N<sub>2</sub> to form HO<sub>2</sub>. This moveable tube is in the center of a 7.5-cm diameter glass flow tube through which ambient air is drawn by a fan with a total sampling flow rate of about 140 l min<sup>-1</sup> and a residence time of 0.1–0.4 s. The OH is injected through radially drilled holes at the end of the movable tube, mixed turbulently into the air flow, and detected by an OH detector at the end of the flow tube. The detection technique is low-pressure laser induced fluorescence, as is used for GTHOS. OH reacts with trace constituents in the air flow and, as the movable tube is drawn further away from the detector, the observed OH signal decreases.

The OH reactivity,  $k_{OH}$ , is the slope of the logarithm of the OH signal,  $S^{OH}$ , as function of the time (the distance divided by the velocity) minus the OH loss to the flow tube's walls,  $k_{wall}$ :

$$k_{OH} = -\Delta \ln(S^{OH}) / \Delta \text{time} - k_{wall} \quad (1)$$

Each decay took 4.3 min, with 20 s at each of 13 steps, 10 s measuring OH plus the background signal and 10 s measuring the background signal. The OH signal decreased by a factor of 10–20 over the 13 steps. Typically, the OH wall loss rate,  $k_{wall}$ , was  $1.5 \pm 0.4 \text{ s}^{-1}$ . Generally, OH mixing ratios were 10–30 pptv inside the glass tubing.

#### 2.4. TOHLM correction technique

Kovacs et al. (2003) and Ren et al. (2003a) discuss the need to correct OH reactivity measurements for the OH-recycling reaction:

Interactive Discussion

When levels of NO are below 1 ppbv, the measured decays are generally linear and the slopes correct to within 10% (Kovacs et al., 2003). However, when ambient levels of NO are higher, the decays have concave curvature as HO<sub>2</sub> reacts with the NO to reform OH. In past studies where the TOHLM instrument was used, NO concentrations infrequently reached levels that required significant corrections or measurements from those times were excluded from further analysis. However, in MCMA during rush hour (05:00–09:00 CST), NO exceeded 50 ppbv 40% of the time and 100 ppbv 12% of the time. This frequent contamination of the decays led to a need for a new correction technique that allows k<sub>OH</sub> to be measured at much higher values of NO than earlier methods (Kovacs et al., 2003).

The rate equation for [OH] is given by the expression:

$$\begin{aligned}\frac{d[\text{OH}]}{dt} &= -k_{\text{OH}}[\text{OH}] + k_{\text{NO}+\text{HO}_2}[\text{NO}][\text{HO}_2] \\ &= -k_{\text{OH}}[\text{OH}] + k_{\text{NO}+\text{HO}_2}[\text{NO}]R[\text{OH}]\end{aligned}\quad (2)$$

where k<sub>OH</sub> is the OH reactivity (s<sup>-1</sup>) and R is the measured [HO<sub>2</sub>]/[OH] ratio. Assuming that the average value for R can be used for each time step, this expression can be integrated to give the value of [OH] at time step t<sub>1</sub>:

$$[\text{OH}]_1 = [\text{OH}]_0 \exp(-k_{\text{OH}}(t_1 - t_0)) \exp(+k_{\text{NO}+\text{HO}_2}[\text{NO}]R(t_1 - t_0)) \quad (3)$$

The desired [OH] value is given by the expression [OH]<sub>0</sub>exp(-k<sub>OH</sub>(t<sub>1</sub> - t<sub>0</sub>)). Thus the corrected [OH] at time t<sub>1</sub> is given by the expression:

$$[\text{OH}]_1^c = [\text{OH}]_1 \exp\left(-\frac{k_{\text{NO}+\text{HO}_2}[\text{NO}][\text{HO}_2]_{0,1}(t_1 - t_0)}{[\text{OH}]_{0,1}}\right) \quad (4)$$

where [OH]<sub>0,1</sub> and [HO<sub>2</sub>]<sub>0,1</sub> are average concentrations of times 0 and 1. Since the observed OH and HO<sub>2</sub> signals are proportional to [OH] and [HO<sub>2</sub>] by the calibration factors, C<sub>OH</sub> and C<sub>HO<sub>2</sub></sub>, which for TOHLM are the same, the OH signal can be corrected for the first time step by the expression:

$$S_1^c = \exp[-(\Delta S_1/S_{0,1})] * S_1 \quad (5)$$

Interactive Discussion

where  $\Delta S_1 = k_{\text{NO}+\text{HO}_2} [\text{NO}] S_{0,1}^{\text{HO}_2} (t_1 - t_0)$  and  $S_{0,1}^{\text{HO}_2}$  is the averaged  $\text{HO}_2$  signal for times  $t_0$  and  $t_1$ .

In order to correct subsequent points, we must realize that the points are not independent of one another. Points  $S_1$  and  $S_2$  are then scaled by  $S_1^c$  by multiplying by  $S_1^c/S_1$ , so that the slope between  $S_1$  and  $S_2$  is preserved but the starting point is  $S_1^c$  (Fig. 2). The correction given in Eq. (4) is then applied to  $S_2$  and the equation for  $S_2^c$  takes the form:

$$S_2^c = \exp[-(\Delta S_1/S_{0,1})] * \exp[-(\Delta S_2/S_{1,2})] * S_2 \quad (6)$$

where  $\exp[-(\Delta S_1/S_{0,1})]$  is simply the  $S_1^c/S_1$  that was calculated in Eq. (5). Each subsequent point is calculated in this manner assuring that each point is scaled to the one before it.

This correction technique was tested in the laboratory (Fig. 3). In this example, NO was  $\sim 75$  ppbv, a normal rush-hour value for Mexico City. The theoretical calculated decay from the NO and ultra zero air mixture is  $14.9 \text{ s}^{-1}$ . The uncorrected decay,  $8.87 \text{ s}^{-1}$ , is only 60% of what is calculated, while the corrected decay is  $14.6 \text{ s}^{-1}$ . Agreement between the calculated and corrected decays is well within the uncertainties of the TOHLM technique and the reaction rate coefficient for  $\text{OH} + \text{NO} + \text{M} \rightarrow \text{HONO} + \text{M}$ .

This correction technique was used on a wide range of NO concentrations, from 10–200 ppbv (Fig. 4). To ensure that this technique would work when other reactants were present, several different concentrations of CO were added to the instrument along with the NO. In all but one case (with and without the addition of CO) the corrected OH decays were within 15% of the theoretical values. However, the correction factor for decays when  $\text{NO} > 100$  ppbv grows to a factor of  $\sim 2$ –3 and becomes more uncertain, since small errors in  $S^{\text{HO}_2}/S^{\text{OH}}$  ratio and in NO become more important. Using estimates of the uncertainties in these two terms and considering the number of points used in the decays, we estimate that the uncertainty in the correction is  $\sim 10\%$ ,  $1\sigma$  confidence. Because the correction for 75 pptv of NO is roughly 1.7, the total absolute uncertainty for the corrected OH reactivity is  $\pm 25\%$ ,  $1\sigma$  confidence, for 75 pptb of NO.

## 2.5. Model description

OH and HO<sub>2</sub> measurements were compared to a constrained steady-state photochemical model, which is briefly described here. A more complete description can be found in Ren et al. (2003b). During the MCMA campaign the following ancillary data were continuously measured: O<sub>3</sub>, CO, SO<sub>2</sub>, NO, NO<sub>2</sub>, CH<sub>4</sub>, HCHO, HONO, temperature, pressure, relative humidity, wind speed, and wind direction. Speciated VOCs were measured at CENICA for four days before and three days after the HO<sub>x</sub> measurements (Lamb et al., 2004) and were measured at other locations while HO<sub>x</sub> was being measured at CENICA. These speciated VOCs were averaged for each half-hour that they were measured over the seven days and summed into VOC types (e.g., internal alkenes) that the model uses. For the model calculations, the abundance for each VOC type was determined by assigning the same fraction of the measured OH reactivity from VOCs to that VOC type and then calculating the VOC type's abundance from that fraction of the OH reactivity divided by the reaction rate coefficient. Since the standard deviation of each fraction was generally less than 35% and the fraction of OH reactivity due to each VOC type was similar at CENICA and three other urban sites, this method should work in an average sense. This method has been shown to give good results between measured and modeled HO<sub>x</sub> in other studies (Ren et al., 2005a, b<sup>1</sup>).

The Regional Atmospheric Chemistry Mechanism (RACM) (Stockwell et al., 1997) was used to calculate the OH and HO<sub>2</sub> concentrations. Kinetic rate coefficients were updated using the results by Sander et al. (2003). Reactions of O<sub>3</sub> with alkenes have been largely revised to represent latest radical yields suggested by recent experiments (Paulson et al., 1999; Rickard et al., 1999; Fenske et al., 2000). Heterogeneous reac-

tions of  $\text{HNO}_3$ ,  $\text{SO}_3$ , and  $\text{N}_2\text{O}_5$  were included in the model. The assumption of steady-state certainly applies to OH, which had a lifetime shorter than 0.1 s and generally to  $\text{HO}_2$ , which has a lifetime less than a few 10 s of seconds.

The model was run with the FACSIMILE software (UES Software Inc). Model input was constrained to the ten-minute average values of  $\text{O}_3$ , NO,  $\text{NO}_2$ , CO,  $\text{SO}_2$ , categorized VOCs, water vapor, temperature, pressure, and photolysis frequencies, which were either measured if available or calculated with the NCAR TUV transfer model and scaled by measured solar UV radiation. The data coverage allowed model calculations only for the period between 14 April and 22 April. OH,  $\text{HO}_2$ ,  $\text{NO}_3$ , organic peroxy radicals ( $\text{RO}_2$ ), and other intermediates were calculated. The uncertainty in this RACM model was estimated to be  $\pm 45\%$  for OH and  $\pm 70\%$  for  $\text{HO}_2$ , with  $2\sigma$  confidence. These uncertainties are based on the combined uncertainties of the kinetic rate coefficients (Sander et al., 2003; Stockwell et al., 1997), the measured chemical concentrations, and the measured and calculated photolysis frequencies, as estimated with a Monte Carlo approach (as in Carslaw et al., 1999).

### 3. Results and discussion

MCMA 2003 was an excellent opportunity to study the atmospheric chemistry of a megacity that has improving air quality but still more air pollution than a typical US or European city. A goal of MCMA was to better understand the sources and chemical transformations of MCMA's air pollution. The suite of measurements assembled at the CENICA site enable calculations of atmospheric reactive constituents, particularly OH and  $\text{HO}_2$ , and of other pollution products. These calculations can then be compared to the observations.

The comparison of the observations at MCMA to those in US urban areas is also instructive. We compare our MCMA observations to our observations taken in New York City (NYC) in July 2001 (Ren et al., 2003a, b). New York City provides a good comparison because it is similar to MCMA in some ways, such as population, but

Interactive Discussion

strikingly different in other ways, such as the ratio of VOCs to NO<sub>x</sub>.

Ozone in MCMA 2003 was significantly greater than ozone in NYC in 2001 (Fig. 5a). The median MCMA O<sub>3</sub> peak of 100 ppbv was twice that of NYC. The maximum value occurred closer to local noon by about 2 h in MCMA than in NYC. Nighttime values were similar in the two locations, with minimum ozone at morning rush hour. In both studies, the observed ozone was less than typical due to atypical weather conditions.

Ozone production depends on both NO<sub>x</sub> and VOCs. The speciated VOCs measured in MCMA 2003 have been compared to the typical US urban values (Lamb et al., 2004), which are not significantly different from the speciation in New York City, although total VOCs in MCMA were ~3 times larger than in the typical US city. However, NO<sub>x</sub> was greater in Mexico City than in NYC only during morning rush hour (Fig. 5b), when, MCMA's median NO<sub>x</sub> was 110 ppbv, almost twice NYC's NO<sub>x</sub>. During the afternoon, both cities had about 20 ppbv of NO<sub>x</sub>. Nighttime NO<sub>x</sub> was typically 20–35 ppbv in both cities. Interestingly, the ratio of peak NO<sub>x</sub> in the two cities – 2 – is similar to the ratio of peak O<sub>3</sub>. The comparison of surface concentrations distorts the differences in NO<sub>x</sub> and VOC emissions, since the midday mixed layer for MCMA was typically 4 km above the surface, while the mixed layer for NYC was typically 1 to 1.5 km. Thus, MCMA's emissions were substantially greater for both NO<sub>x</sub> and VOCs.

### 3.1. OH reactivity measurements

In MCMA, the OH reactivity,  $k_{OH}$ , had a strong peak of  $\sim 120 \text{ s}^{-1}$  during morning rush hour,  $25 \text{ s}^{-1}$  during midday, and  $\sim 35 \text{ s}^{-1}$  at night (Fig. 6). It is also similar to the diurnal behavior of NO<sub>x</sub>, which is consistent with a large transportation source of both OH reactivity and NO<sub>x</sub>. This behavior contrasts with the OH reactivity in NYC, which was typically  $20 \text{ s}^{-1}$  the entire time, with a small increase during morning rush hour (Fig. 6). The MCMA morning peak is about 5 times what was found in NYC.

The comparison of the measured OH reactivity to the calculated OH reactivity is complicated by the timing of the two measurements during the study. Speciated VOCs

Interactive Discussion

were measured just before and just after the period that OH reactivity was measured. A direct comparison is thus not possible. However, when the measured and calculated OH reactivity are plotted as a function of time of day, they are similar in absolute value and diurnal behavior (Fig. 6).

5 From calculations,  $75 \pm 16$  % of this reactivity is due to VOCs during daylight hours with the lowest values when  $\text{NO}_2$  is greatest at 09:00 CST, while  $84 \pm 7\%$  is due to VOCs during night. Examining the OH reactivity due only to VOCs, the ratio of the OH reactivity per ppbC of VOCs was  $0.056 \pm 0.017 \text{ s}^{-1} \text{ ppbC}^{-1}$  in MCMA, but was  $\sim 3$  times greater at  $0.15 \pm 0.02 \text{ s}^{-1} \text{ ppbC}^{-1}$  in NYC. This difference is consistent with the  
10 differences mainly in the alkane abundances between MCMA and typical US cities (Lamb et al., 2004). NYC in 2001 had approximately 1.5 times less VOCs than the typical US urban area.

### 3.2. OH and $\text{HO}_2$ : measured and modeled values

OH was measured on 21 days in Mexico City from 5 April to 26 April 2003 (Fig. 7);  $\text{HO}_2$   
15 was measured on 18 days from 8 April to 26 April 2003 (Fig. 8). The NO addition to the  $\text{HO}_2$  axis was deliberately delayed so that any potential interference that it might cause could be detected as a change in the OH measurement. No change was detected. OH was fairly consistent from day-to-day, with midday peak values of 0.25–0.4 pptv ( $(5\text{--}8) \times 10^6 \text{ cm}^{-3}$ ). The effects of clouds on OH production can be seen in the reduction  
20 in OH on several afternoons. Variability was greater for  $\text{HO}_2$  than for OH. Peak  $\text{HO}_2$  varied from 15 pptv ( $\sim 3 \times 10^8 \text{ cm}^{-3}$ ) to 60 pptv ( $\sim 12 \times 10^8 \text{ cm}^{-3}$ ).

The OH diurnal cycle becomes more distinct when OH is plotted as a function of time-of-day (Fig. 9a and c). The median OH peaks at 0.35 pptv ( $\sim 7 \times 10^6 \text{ cm}^{-3}$ ) at local noon. The nighttime values ranged from 0.05 pptv ( $\sim 1 \times 10^6 \text{ cm}^{-3}$ ) to below the  
25 detection limit (0.01 pptv or  $2 \times 10^5 \text{ cm}^{-3}$ ) for 1-min measurements.

The observed OH in MCMA is similar to the observed OH in NYC, despite the large differences in OH reactivity, sunlight, and  $\text{HO}_x$  production rates between the two cities (Fig. 9a). The peak value in New York City is shifted 2 h past solar noon, but at 0.28 pptv

Interactive Discussion

is only 20% lower than the average peak OH for MCMA.

The modeled OH shows similar behavior to the measured OH (Fig. 9c). The measured-to-modeled OH ratio is 1.07 during morning rush hour (05:00–09:00 CST), 0.77 during midday (10:00–14:00 CST), and 1.07 at night (20:00–04:00 CST). Daytime median modeled OH agrees with the daytime median OH measurements to well within the measurement uncertainty ( $\pm 32\%$ ,  $2\sigma$  confidence) and the model uncertainty. The linear fit of measured OH as a function of modeled OH has a slope of 0.65, and intercept of 0.026 pptv, and a correlation coefficient of 0.80. This slope is consistent with the tendency in the measured-to-modeled OH ratio, since the measured OH tends to be larger during the night and morning when OH is low while the modeled OH tends to be greater during midday, when the OH is greater. Relatively good agreement between median measured and modeled OH at night contrasts with poor agreement exceeding a factor of 5 in some other urban environments (Martinez et al., 2003; Ren et al., 2003b).

The HO<sub>2</sub> peak is narrower than the OH peak and is shifted one hour later. HO<sub>2</sub> persisted at ~5 pptv (0.5 to 20 pptv) during the night. HO<sub>2</sub> has a diurnal profile that peaked at ~40 pptv at 13:00, and decreased to less than 0.5 pptv at sunrise, when HO<sub>x</sub> production was just beginning to increase but when copious rush-hour NO effectively scavenged HO<sub>2</sub>.

The HO<sub>2</sub> in MCMA was generally ten times larger than the HO<sub>2</sub> was in NYC (Fig. 9b). This large difference results from the large difference in the HO<sub>x</sub> sources, although the MCMA photolysis frequencies were only about twice those in NYC. The big difference is the greater amount of HCHO in MCMA. It peaks at ~20 ppbv in the morning (R. Volkamer, private communication, 2005), represents about 40% of the HO<sub>x</sub> source, and is about 15 times larger in MCMA than in NYC during midday. Ozone, which is twice as large in MCMA as in NYC, also contributes to the difference in HO<sub>x</sub>. The HO<sub>x</sub> sink, which is predominantly the reaction  $\text{OH} + \text{NO}_2 + \text{M} \rightarrow \text{HNO}_3 + \text{M}$ , is comparable in the two cities except during morning rush hour, when it is twice as large in MCMA. The difference in OH reactivity translates directly into the difference in HO<sub>x</sub>, which in turn

Interactive Discussion

determines the ozone production rates.

The model simulates the median measured HO<sub>2</sub> to well within the measurement and modeling uncertainties (Fig. 9d). The midday measured-to-modeled ratio is 0.79; the nighttime ratio is 1.25. During morning rush hour, the observed-to-modeled ratio is 1.17. The linear fit of measured HO<sub>2</sub> as a function of modeled HO<sub>2</sub> has a slope of 0.70, and intercept of 3.4 pptv, and a correlation coefficient of 0.64. The model appears to produce too much HO<sub>x</sub> during the daytime.

These MCMA HO<sub>x</sub> measurements are a good example of the buffering effects of the OH production and loss processes. Over the course of the study, HO<sub>2</sub> peak values varied greatly from day-to-day, indicating dramatic changes in HO<sub>x</sub> sources, but OH peak values remained relatively unchanged, as can be seen by comparing Figs. 7 and 8 and by comparing the MCMA and NYC median HO<sub>x</sub> values in Fig. 9. That HO<sub>2</sub> is much more sensitive to HO<sub>x</sub> sources and sinks than OH suggests that HO<sub>2</sub> must be measured along with OH to really test and understand the radical chemistry.

For MCMA 2003 midday HO<sub>2</sub>/OH was typically 120, with low values of 10–15 during morning rush hour and high values of 200 at night (Fig. 10). This behavior is quite different from New York City, where the ratio was typically ~15 at all times (Ren et al., 2003a). The difference in the midday HO<sub>2</sub>/OH ratio between MCMA and NYC is due to differences in NO, which was typically less than 1 ppbv in MCMA but 5 ppbv or higher in NYC, and the OH reactivity, which in MCMA was typically 1.5 times that in NYC. When HO<sub>x</sub> cycling is faster than HO<sub>x</sub> production and loss, the HO<sub>2</sub>/OH ratio is approximately given by the equation:

$$\frac{[\text{HO}_2]}{[\text{OH}]} \approx \frac{k_{\text{OH}}[\text{OH}]}{k_{\text{NO}+\text{HO}_2}[\text{NO}]} \quad (7)$$

Increasing the numerator in Eq. (7) by 1.5 and decreasing the denominator by ~5 provides the difference in the MCMA and NYC HO<sub>2</sub>/OH ratios.

The measured HO<sub>2</sub>/OH ratios display the same dependence on NO as the modeled ratio (Fig. 10) for NO between 1 and 100 ppbv. Both the measured and modeled ratios

Interactive Discussion

vary approximately as the  $\frac{1}{2}$  power of NO, whereas an NO power dependence of 1 to 2 is expected. This less-than-theory power dependence comes from the co-emission with NO of atmospheric constituents that react with OH, thus increasing HO<sub>2</sub>. While such good agreement between the measured and modeled ratio is expected, this behavior is not observed in some other urban areas. Typically, the measured HO<sub>2</sub>/OH has had a much shallower slope with respect to NO than the modeled ratio does (Ren et al., 2003; Martinez et al., 2003; Emmerson, 2005).

### 3.3. OH production and loss

MCMA's OH reactivity of 20 s<sup>-1</sup> during most of the day and 120 s<sup>-1</sup> at morning rush hour implies OH lifetimes of 50 ms to 8 ms. This lifetime is much shorter than the time scales for other processes, including mixing of emissions, changes in photolysis, and other chemistry. As a result, OH should always be in steady-state. The OH production should equal the OH loss:

$$P(\text{OH}) = 2J_{\text{O}_3} f [\text{O}_3][\text{H}_2\text{O}] + J_{\text{HONO}} [\text{HONO}] + k_{\text{NO}+\text{HO}_2} [\text{NO}][\text{HO}_2] + k_{\text{O}_3+\text{VOC}} [\text{O}_3][\text{VOC}] + \text{other smaller terms} = k_{\text{OH}} [\text{OH}] = L(\text{OH}) \quad (8)$$

$f$  is the fraction of O(<sup>1</sup>D) that is produced from O<sub>3</sub> photolysis and reacts with H<sub>2</sub>O to produce OH. The OH loss is determined simply from the product of [OH] and the OH reactivity, both of which are measured. Over 80% of the OH production is controlled by [HO<sub>2</sub>] and [NO], both of which are measured. The first three OH production terms were calculated from measurements; the fourth term, OH production from O<sub>3</sub> and alkenes, was taken from model results and was less than 5% of the total.

P(OH) and L(OH) are in balance to within the combined 2σ uncertainties of the OH production and loss terms (Fig. 11). The difference L(OH) – P(OH) should be zero for the entire day, but it is actually slightly negative during morning rush hour (05:00–09:00 CST), implying greater-than-expected production. Smaller L(OH) – P(OH) differences at morning rush hour were observed in Nashville (Martinez et al., 2003) and in New York City (Ren et al., 2003a).

Interactive Discussion

These differences at morning rush hour are not beyond the measurement uncertainties, and yet they are persistent from study to study. For MCMA between 07:00 and 08:00 CST, OH production is double the OH loss. Previous attempts to explain these differences with instrumental artifacts for HO<sub>2</sub> have failed (Ren et al., 2004); however, it is possible that our laboratory tests of the correction algorithm for HO<sub>2</sub>+NO→OH+NO<sub>2</sub> do not apply to MCMA air, with its more complex composition. This explanation, however, seems unlikely.

If the measurements are correct, then the imbalance in the OH production and loss at morning rush hour indicates problems with known urban photochemistry. We are left with the conclusion that some aspect of the HO<sub>x</sub>-NO<sub>x</sub> photochemistry may need re-examination. One solution would be that some products of the reaction HO<sub>2</sub>+NO are not OH+NO<sub>2</sub>. Instead, this imbalance provides evidence that some of the HO<sub>2</sub>+NO reaction results either in HO<sub>x</sub> removal or couples with another reaction that rapidly cycles back to HO<sub>2</sub> without going through OH. The uncertainty in the MCMA measurements does not allow us to distinguish between HO<sub>x</sub> removal or rapid cycling. A study of the imbalance in the NO<sub>x</sub> photostationary state led Volz-Thomas et al. (2003) to a similar and possibly related conclusion: an unknown process is converting NO to NO<sub>2</sub> without resulting in ozone production.

### 3.4. Instantaneous O<sub>3</sub> production

The net instantaneous O<sub>3</sub> production is in some ways a better indicator of the connection between ozone precursors and ozone than is the ozone mixing ratio itself (Kleinman et al., 2000). Instantaneous ozone production is not subject to the uncertainties in physical processes like horizontal advection, planetary boundary layer height changes, entrainment of free-tropospheric air, and dry deposition. On the other hand, because it does not take these physical processes into account, it is a poor indicator of the actual ozone mixing ratios that will occur. Never-the-less, it does provide insight into the chemical processes that create ozone at the CENICA site.

The net instantaneous photochemical O<sub>3</sub> production can be calculated by the equa-

tion:

$$P(O_3) = k_{HO_2+NO}[NO][HO_2] + \sum k_{RO_2i+NO}[NO][RO_{2i}] - k_{OH+NO_2+M}[M][NO_2][OH] - P(RONO_2) \quad (9)$$

For urban environments like MCMA, including the  $NO_2$  lost to  $HNO_3$  or organic nitrate ( $RONO_2$ ) formation can offset  $\sim 10\%$  of the ozone production and must be included. If  $P(O_3)$  is calculated only from the measured quantities  $HO_2$ ,  $NO$ ,  $OH$ , and  $NO_2$ , then only the first and the third terms are retained. This reaction, of course, assumes that all of  $HO_2+NO$  forms  $OH+NO_2$  and that  $NO_2$  is photolyzed to produce ozone.

For the period between 14 April and 22 April when the measurement suite was complete enough for model runs,  $P(O_3)$  calculated from measured  $HO_2$  peaked at 48 ppbv  $hr^{-1}$  while  $P(O_3)$  calculated from modeled  $HO_2$  peaked at 86 ppbv  $hr^{-1}$  (Fig. 12). Both peaks are broad and achieve maximum values near 10:00 CST. Peak values on some days were greater than 100 ppbv  $hr^{-1}$ . The greater modeled  $P(O_3)$  in late morning is due to the greater modeled  $HO_2$  then.

The  $NO_x$  peak at morning rush hour is mainly due to fresh  $NO$  emissions (Fig. 5). Beginning at about 05:00 CST,  $O_3$  was drawn down by the reaction with  $NO$  to form  $NO_2$ , but the sum of  $NO_2+O_3$  remained relatively constant. As  $P(O_3)$  began to increase at 06:00 CST,  $NO_2+O_3$  began to increase, but more than 90% of the produced  $O_3$  was partitioned into  $NO_2$  by reaction with  $NO$ .  $O_3$  did not begin to really rise until about 07:30 CST, when  $NO$  had fallen to half its peak value and  $J(NO_2)$  had climbed to 16% of its peak value. Thus, the sum of  $NO_2+O_3$  rose along with  $P(O_3)$ , while the  $O_3$  rise appears to have been delayed by about 1.5 h (Fig. 12).

In New York City, the median mid-morning  $P(O_3)$  from  $HO_2$  was 12 ppbv  $hr^{-1}$ , peaking at 11 EDT. On a few days,  $P(O_3)$  from  $HO_2$  reached as high as 50 ppbv  $hr^{-1}$ , but on many days, its peak value was less than 10 ppbv  $hr^{-1}$ . This ozone production rate from  $HO_2$  is about five times smaller than that observed in MCMA. The differences in the measured  $HO_2$  in MCMA and NYC is the difference in  $P(O_3)$ .

$P(O_3)$  is expected to increase until  $NO$  reaches a few ppbv, after which  $P(O_3)$  decreases as  $HO_2$  begins to decrease greater than linearly with  $NO$ . In some environ-

Interactive Discussion

ments,  $P(O_3)$  did not have the expected decrease as NO exceeded a few ppbv (Martinez et al., 2003; Ren et al., 2003a, 2005a). This unexpected behavior can be directly attributed to the less-than-expected decrease in  $HO_2$  or  $HO_2 + RO_2$  at greater NO. In MCMA 2003, the behavior of  $HO_2$  as a function of NO is not dramatically different from the model (see Fig. 12). If the measurements and models are segregated into data for which  $HO_x$  production exceeded  $2 \times 10^7$  molecules  $cm^{-3} s^{-1}$ , which are typically mid-day values, and for  $HO_x$  production for  $10^6 - 10^7$  molecules  $cm^{-3} s^{-1}$ , which is typical of morning and evening rush hour, the  $P(O_3)$  calculated from measured and modeled  $HO_2$  show similar behavior as a function of NO (Fig. 13). The data are sparse, but  $P(O_3)$  appears to peak when NO is 20 to 30 ppbv.

It is not clear why  $P(O_3)$  calculated from measured  $HO_2$  appears to behave as expected for MCMA 2003 while it did not for other urban areas. New York City in winter-time is an extreme example of unexpected behavior (Ren et al., 2005a). It has been speculated that the greater-than-expected  $HO_2$  at greater NO is due to unknown  $HO_x$ - $NO_x$  chemistry. Since the greatest difference between NYC and MCMA is the VOC levels, it may be that the rapid cycling of  $HO_x$  through VOC chemistry reduces the impact of the unknown  $HO_x$ - $NO_x$  chemistry on  $HO_2$ .

The cumulative daily surface ozone production from  $HO_2$  at the CENICA site was calculated to be 319 ppbv by measurement and 335 ppbv by model. The model suggests that the total ozone production from  $HO_2$  and  $RO_2$  was 629 ppbv, since modeled  $RO_2$  was typically 1.5 times modeled  $HO_2$ . These cumulative values are for the CENICA site only. To relate ozone production to observed ozone requires the knowledge of the temporal and spatial variations of  $P(O_3)$  and  $O_3$  throughout the MCMA.

#### 4. Summary and conclusions

The MCMA 2003 study stretched the envelope of the pollution levels for which such a complete set of atmospheric measurements that included OH and  $HO_2$  have been obtained. We summarize several conclusions from this study.

Interactive Discussion

First, even in an environment with such high loadings of  $\text{NO}_x$  and VOCs, steady-state photochemical models were generally able to simulate the measured OH and  $\text{HO}_2$ . The model tends to produce too little OH and  $\text{HO}_2$  during night and morning rush hour and too much during midday. We are investigating to see if these differences are due to errors in the  $\text{HO}_x$  sources or the  $\text{HO}_x$  in the model. The agreement between the measured and modeled  $\text{HO}_x$  is as good as or better than that obtained in other urban environments (George et al., 1999; Martinez et al., 2003; Ren et al., 2003b; Heard et al., 2004).

Second, a surprising result is the good agreement between the measured and modeled  $\text{HO}_2/\text{OH}$  ratio as a function of NO. This agreement is better than we have seen in any other environment where NO exceeded a few ppbv. The difference between these other urban areas and MCMA is not particularly the  $\text{NO}_x$  abundance, which is similar to that in New York City, but instead is the large amounts of VOCs, which result in high OH reactivities.

Third, while the OH sources and sinks are both substantially increased over those in US cities, the resulting OH is similar to that observed in US cities. Not so for  $\text{HO}_2$ , which was greater in MCMA than in US cities and thus directly responsible for the differences seen in the ozone levels between MCMA and US cities.

Fourth, the OH reactivity was higher than we have observed in any other environment, reaching more than  $120\text{ s}^{-1}$  in morning rush hour. Our correction scheme for  $\text{HO}_2 + \text{NO} \rightarrow \text{OH} + \text{NO}_2$  allows OH reactivity measurements in much more polluted environments than before. While the overlap between measured OH reactivity and speciated VOCs was poor, the diurnal patterns and values are qualitatively similar. This observation is consistent with our observations in New York City and Houston, Texas, unlike our measurements in Nashville (Kovacs et al., 2003) and other measurements in Tokyo (Sadanaga et al., 2004), both of which were 30% greater than calculated OH reactivity.

Fifth, the balance between OH production and OH loss is generally consistent with the expected OH steady state balance. A possible exception is during morning rush

hour when OH production exceeds OH loss by as much as a factor of two. While the differences are not statistically significant, they do bear watching because they suggest errors in HO<sub>x</sub>-NO<sub>x</sub> photochemistry.

5 Sixth, the apparent good agreement between the net instantaneous ozone production calculated from measured HO<sub>2</sub> and from modeled HO<sub>2</sub> stands in contrast to previous urban studies. Examining the differences between the atmospheric compositions in these different environments may illuminate the cause of the unexpected results in the other studies.

10 Finally, the combination of high OH reactivity, abundant sunlight, and NO<sub>x</sub> at morning rush hour jump starts ozone production, which from HO<sub>2</sub> alone reached ~50 ppbv hr<sup>-1</sup> by mid-morning. Similar results are found by R. Volkamer (private communication, 2005). Had the meteorological conditions not produced afternoon clouds, occasional rain, and below normal temperatures, midday ozone levels would have been greater.

15 *Acknowledgements.* We thank the entire MCMA team for the support they provided us during the MCMA 2003 campaign and for the stimulating discussions at the science workshop. We also thank our colleagues for the use of their data for our model calculations. This work was supported by NSF Atmospheric Chemistry grants (ATM-0209972 and ATM-308748) and the Comisión Ambiental Metropolitana of Mexico. R. Volkamer acknowledges the Henry and Camille Dreyfus Foundation for a Dreyfus postdoctoral fellowship.
